## **EARLY ONLINE RELEASE**

This is a preliminary PDF of the author-produced manuscript that has been peer-reviewed and accepted for publication. Since it is being posted so soon after acceptance, it has not yet been copyedited, formatted, or processed by AMS Publications. This preliminary version of the manuscript may be downloaded, distributed, and cited, but please be aware that there will be visual differences and possibly some content differences between this version and the final published version.

The DOI for this manuscript is doi: 10.1175/BAMS-D-15-00035.1

The final published version of this manuscript will replace the preliminary version at the above DOI once it is available.

If you would like to cite this EOR in a separate work, please use the following full citation:

24 **Motivation**

25 The way in which the climate changes in response to increases in anthropogenic  
26 greenhouse gases is one of the foremost questions for the scientific community, policy  
27 makers and the general public. A key approach for examining climate, especially how it  
28 will change in the future, uses complex computer models that include atmosphere, ocean,  
29 sea ice and land components. Some models also simulate additional facets of the earth  
30 system, including marine chemistry and biology. Model simulations indicate that  
31 temperatures have warmed over the past century, and will continue to rise into the future  
32 due to greenhouse gas forcing (IPCC, 2014). However, the very large number of model  
33 simulations, the sheer volume of data they have generated, and output that might not be  
34 directly relevant for many applications can make it extremely difficult for potential users  
35 to access, view and evaluate the data.

36 While useful web tools exist for viewing model-simulated climate change including  
37 the “Climate Reanalyzer”, “Climate Wizard”, “National Climate Change Viewer”,  
38 “KNMI Climate Change Atlas” and “Climate Variability and Diagnostics Package”, the  
39 Climate Change Web Portal offers some unique capabilities, including examination of  
40 model bias, inter-model variability, changes in variance, ocean physical and  
41 biogeochemical model output.

42 The Climate Change Web Portal (<http://www.esrl.noaa.gov/psd/ipcc/>) was developed  
43 by the NOAA/ESRL Physical Sciences Division to access and display the large volumes  
44 of climate and earth system model output from the Coupled Model Inter-comparison  
45 Project Version 5 (CMIP5, Taylor et al. 2012, van Vuuren et al. 2011) that informed the  
46 recently released Intergovernmental Panel on Climate Change (IPCC) report. The portal

47 has two components that encompass *i)* land and rivers or *ii)* oceans and marine  
48 ecosystems. Recent changes in Federal agency directives and programmatic mandates  
49 require Federal managers to consider climate change in water resources and  
50 environmental planning. As a result, resource managers are now required to make  
51 judgments regarding which aspects of climate projection information are applicable to a  
52 given decision, including decisions to modify system operations, invest in new or  
53 improved infrastructure, and establish long-term management objectives. The web portal  
54 provides scientists, resource managers, and stakeholders a framework to evaluate and  
55 interpret the models by comparing them to observations (land/rivers portion) during the  
56 historic record and view how they project climate change in the future. To this end,  
57 Federal water and fisheries managers have already used this tool in decision making  
58 processes. The goal of this manuscript is to introduce the reader to the capabilities of the  
59 web portal.

60

## 61 **Methods and Examples**

62 By pre-processing the model output and utilizing a number of software tools, the  
63 web-portal allows users to quickly display maps and time series via a series of menu  
64 options. As a first step, output from the CMIP5 models, which have different horizontal  
65 resolutions, are interpolated to a 1° lat-lon grid to allow for inter-model comparisons.  
66 Statistics for different climate metrics are then computed on the common grid. A  
67 combination of software languages including Javascript, Python and NCAR's Command  
68 Language (NCL), are used to access the NetCDF files to generate an image in real time.  
69 From the portal, set of menus allows the user to choose: *i)* an individual model or the

70 model ensemble mean; *ii*) an experiment (i.e., past or future greenhouse gas forcing); *iii*)  
71 fields to display such as precipitation and ocean temperature at 100 m depth; *iv*) statistics,  
72 such as the mean, median, 90 percentile (%), for the land component and standardized  
73 anomalies for the ocean component; *v*) annual mean or three-month seasons; *vi*) time  
74 periods in the 20<sup>th</sup> and 21<sup>st</sup> century, and *vii*) pre-defined or a user-defined region. Once  
75 the menu choices are selected, either four maps or two time series are displayed.

76 We illustrate the features of the system via examples of the land/river and ocean  
77 components of the portal. The first example (Fig. 1) shows the 90<sup>th</sup> percentile of the  
78 surface air temperature (SAT, °C) during JJA for the years 1911-2005 (the SAT of the  
79 10<sup>th</sup> warmest summer in each grid square over the 95-year period) over North America  
80 from *i*) observations ([University of Delaware Terrestrial Air Temperature](#), upper left) and  
81 *ii*) the ensemble mean of the CMIP5 models (upper right), *iii*) the difference between the  
82 two, indicating the model bias (lower left) and *iv*) the difference between the 90% SAT in  
83 the RCP 8.5 experiment during the 21<sup>st</sup> century (2006-2100) minus the values in the  
84 historical period (1911-2005), indicating the climate change signal (lower right). The  
85 ensemble model mean generally matches the observed pattern of very warm summer  
86 seasons, where the 90% exceeds 25°C over the southwest US and the southern Great  
87 Plains, with values less than 20°C over the Rocky Mountains and northwest US.  
88 However, on average the models are too warm, by approximately 0.5°-2°C, over most of  
89 the Great Plains but slightly cooler than observed over the southeast US. The bias has a  
90 complex pattern over Mexico and the western US due in part to the smoothed  
91 representation of mountains in climate models. SAT extremes in JJA are more likely over

92 the entire domain in the 21<sup>st</sup> century relative to the 20<sup>th</sup>, especially away from the coasts  
93 where the change in the 90% exceeds 5°C between 35° and 55°N.

94 The web portal can also be used to examine time varying changes. For example, the  
95 30-year running mean of observed and simulated precipitation (mm) over the entire year  
96 for the New England watershed or Hydrologic Unit Code (HUC, a hierarchical  
97 representation of river basins) is presented in Fig. 2. In general the models simulate more  
98 precipitation over New England during the 20<sup>th</sup> century than observed ([GPCC version 5](#)),  
99 although the observed values are within the full range of the CMIP5 models (left panel).  
100 The right panel shows the observed and simulated precipitation values with their  
101 respective means over the 1901-2005 period removed (“anomaly”). Both observations  
102 and the models indicate an increase in precipitation for New England. While the spread in  
103 the precipitation increases among the models towards the end of the 21<sup>st</sup> century, all  
104 model simulations indicate an increase in precipitation by 2100. Enhanced precipitation,  
105 which is especially prominent in winter (not shown), could lead to increased flooding  
106 when the snow melts in late winter/early spring.

107 Due to the absence of adequate observations for some ocean fields, the plots for the  
108 ocean component of the web portal are based solely on the climate model output. The  
109 annual and ensemble mean 0-700 m heat content ( $\text{J m}^{-2}$ ) in the North Pacific Ocean is  
110 shown in Fig. 3, including the: *i*) mean during the historical period (1956-2005) (upper  
111 left), *ii*) mean climate change signal given by the heat content in 2006-2055 minus 1956-  
112 2005 (upper right), *iii*) year-to-year variability as indicated by the standard deviation  
113 during the historical period (lower left) and *iv*) ratio of the interannual variance in the  
114 future relative to the historical period (lower right). The mean heat content is relatively

115 high in the subtropics and low in high latitude with a tight gradient in between at  $\sim 40^\circ\text{N}$   
116 especially in the western side of the basin. The heat content is indicative of the wind  
117 driven upper ocean circulation with subtropical and subpolar gyres and the  
118 Kuroshio/Oyashio Extension current along the tight gradient between them. The latter is  
119 a region of enhanced interannual variability relative to the rest of the North Pacific  
120 Ocean. The difference between periods indicates that the heat content of the entire North  
121 Pacific increases in the first half of the 21<sup>st</sup> century. However, the increase is not uniform  
122 but is concentrated along  $40^\circ\text{N}$  in the western Pacific, suggesting either a northward shift  
123 of the Kuroshio/Oyashio current extension and/or an increase in the surface heat flux into  
124 the ocean or an increase convergence of heat near the front (Wu et al. 2012). Finally, the  
125 interannual heat content variability decreases during 2006-2055 relative to 1956-2005  
126 over most of the North Pacific except at  $\sim 45^\circ\text{N}$ , just north of the front during the 20<sup>th</sup>  
127 century.

128 Annual average sea surface salinity (SSS) fields over the North Atlantic as simulated  
129 by NCAR's Community Climate System model, version 4 (CCSM4, Gent et al. 2011) are  
130 shown in Fig. 4. The climatological mean SSS during 1956-2005 exhibits a maximum ( $>$   
131 36 psu) in the subtropics and the Mediterranean, with higher values in the western  
132 Atlantic and minimum values ( $<$  33 psu) over most of the Arctic Ocean. The CCSM4  
133 indicates that SSS will increase in the subtropics and decrease north of  $\sim 40^\circ\text{N}$  in the 21<sup>st</sup>  
134 relative to the 20<sup>th</sup> century. The standard deviation of SSS is maximized in the northwest  
135 Atlantic near  $40^\circ\text{N}$ , at the boundary between the salty subtropical and relatively fresh  
136 subpolar gyres, and in the vicinity of the sea ice edge that extends from north of Iceland  
137 northeastward to Svalbard. The 21<sup>st</sup>/20<sup>th</sup> century SSS standard deviation is positive over

138 most of the Atlantic north of 30°N suggesting that salinity variability will increase over  
139 much of the North Atlantic in the future especially between Iceland and Great Britain.

140 Earth system models in the CMIP5 archive simulate aspects of the biogeochemistry in  
141 the ocean, including primary production by phytoplankton that grow via the uptake of  
142 carbon and other inorganic molecules using energy provided by sunlight. Generally  
143 marine ecosystem models simulate several classes of phytoplankton, although the number  
144 of kinds of that are represented differ between models. The annual average primary  
145 production from all phytoplankton classes over the upper 150 m is shown for the Arctic  
146 and subpolar oceans (> 50°N) in Fig. 5. In the historical period, average 1956-2005, the  
147 North Atlantic, North Pacific and Bering Sea are very productive, while the central Arctic  
148 is not. Several factors influence primary productivity including light, and temperature,  
149 which are limiting at high latitudes, and nutrients, which limit phytoplankton growth in  
150 midlatitudes and the tropics. The primary productivity during the historical period  
151 indicates that conditions are conducive for phytoplankton growth during spring through  
152 fall in subpolar regions but ice cover, cold temperatures and long periods without  
153 sunlight, limit the annual production in the central Arctic and on both sides of Greenland.  
154 Productivity is enhanced north of Europe where warm water from the Atlantic enters the  
155 Arctic Ocean. The climate change signal (2050-2099 minus 1956-2005) exhibits reduced  
156 primary productivity over the North Atlantic and Gulf of Alaska and increased  
157 productivity in the Arctic, the Sea of Okhotsk and most of the Bering Sea. The largest  
158 increase in productivity in the Arctic coincides with the largest decrease in sea ice (not  
159 shown), which enables more light to reach the ocean allowing for more photosynthesis.  
160 The decrease in productivity in the North Atlantic and Gulf of Alaska may result from an

161 increase in stratification, due to a freshening and warming near the surface (see  
162 Capotondi et al. 2012), which reduces the amount of nutrients mixed into the upper ocean  
163 from deeper ocean.

164

## 165 **Summary**

166 While the Climate Change web-portal was initially designed for hydrologic and  
167 fishery applications, we anticipate that it will be useful to a wide range of users. To that  
168 end, we have included additional information including tutorials and metadata accessible  
169 through help links on the portal. In addition, the derived fields used to make the plots can  
170 be downloaded as a netCDF file, so users can use their own software package to create  
171 plots. The portal is designed so that more variables, experiments, statistics, and features  
172 can be added in the future. Currently there are some capabilities such as comparing  
173 models side by side, comparing ocean model output with observations and comparing the  
174 variability of the climate change signal among all the models that are not possible. We  
175 plan to add these features and enhance web-portal tutorials in the future. We feel that this  
176 tool provides a useful framework for users to assess current and future changes in CMIP5  
177 climate simulations. More details on climate modeling, the IPCC report, the CMIP5  
178 experiments and observational datasets can be found here:

179 <http://www.esrl.noaa.gov/psd/ipcc/references.htm>.
